(Received 7 March 2008; published 13 February 2009)

We revisit the dynamics of a gene repressed by its own protein in the case where the transcription rate does not adapt instantaneously to protein concentration but is a dynamical variable. We derive analytical criteria for the appearance of sustained oscillations and find that they require degradation mechanisms much less nonlinear than for infinitely fast regulation. Deterministic predictions are confirmed by stochastic simulations of this minimal genetic oscillator.

DOI: 10.1103/PhysRevLett.102.068104 PACS numbers: 87.18.Vf, 82.40.Bj, 87.16.Yc

For simplicity, we study the case of an elementary kinetic equation describing regulation through protein-DNA binding [24], which we, however, prefer to view as a minimal description of transcriptional memory in more complex mechanisms. We derive an analytical expression of the oscillation threshold, and show that when the gene response time is appropriately tuned, the one-gene circuit can be destabilized (and oscillations induced) by degradation mechanisms much less nonlinear than for infinitely fast regulation. This result provides new insights into the interplay of nonlinearity and time delay. Stochastic simulations confirm that the main results of our analysis carry over to low-copy-number situations.

Our study is based on the following three-variable model describing the genetic circuit represented in Fig. 1:

\[
\begin{align*}
\dot{G} &= \theta_0 (1 - G) - \alpha_0 C(P) G, \quad (1a) \\
\dot{P} &= n \dot{G} + \beta_0 M - \delta_p F(P), \quad (1b) \\
\dot{M} &= \mu_0 + \lambda_0 G - \delta_M H(M), \quad (1c)
\end{align*}
\]

FIG. 1 (color online). Reaction diagram of the self-regulated gene circuit.
where $G$, $P$, and $M$ represent gene activity, protein and RNA copy numbers. Equation (1a) formally describes the kinetics of protein-DNA binding at rate $\alpha_0$ and unbinding at rate $\theta_0$. Possible cooperation effects are taken into account via the function $C(P)$ and the number $n$ of proteins binding DNA. Single-protein regulation corresponds to $C(P) = P$, $n = 1$. More generally, Eq. (1a) is a minimal model for the dynamics of an effective gene activity $G$ slowly relaxing towards an equilibrium value given by the gene regulation function $G = \frac{1}{1 + C(P)/C(P_0)}$, with $P_0$ the half-expression threshold. Such a model can be obtained as the leading approximation of a mechanistic model of transcription including all processes concurring to gene expression (e.g., protein-DNA interaction, formation of open complex, polymerase recruitment, chromatin remodeling...) when there is a dominant limiting step.

Equation (1a) causes gene activity $G$ to lag fast changes in protein level, and plays a dynamical role similar to explicit time delays [18–20] or to transport equations [14]. In Eq. (1b), the three terms correspond to binding or unbinding, translation, and degradation. Equation (1c) describes transcription at rate $\mu_0 + \lambda_0G$ and RNA degradation. In order to understand how oscillations can be induced by tuning protein and RNA degradation, we derive the oscillation criterion for arbitrary degradation functions $F(P)$ and $H(M)$ with unit derivative at zero, $\delta_P$ and $\delta_M$ being the low-copy-number degradation rates.

By renormalizing time, variables, parameters, cooperativity and degradation functions according to

$$t = \frac{t'}{\delta_M}, \quad G = g, \quad P = pP_0, \quad M = mM_0,$$

$$P_0 = C^{-1}\left(\frac{\theta_0}{\alpha_0}\right), \quad M_0 = \frac{\delta_P P_0}{\beta_0}, \quad \theta = \frac{\theta_0}{\delta_M},$$

$$\alpha = \frac{\theta_0}{P_0 \delta_M}, \quad \delta = \frac{\delta_P}{\delta_M}, \quad \lambda = \frac{\lambda_0}{M_0 \delta_M}, \quad \mu = \frac{\mu_0}{M_0 \delta_M},$$

$$c(p) = \frac{C(P)}{C(P_0)}, \quad f(p) = \frac{F(P)}{P_0}, \quad h(m) = \frac{H(M)}{M_0}. \quad (2a)$$

Equations (1) can be rewritten in dimensionless form

$$g' = \theta[1 - g(1 + c(p))], \quad (3a)$$

$$p' = n\alpha[1 - g(1 + c(p))] + \delta[m - f(p)], \quad (3b)$$

$$m' = \mu + \lambda g - h(m), \quad (3c)$$

where $x' = dx/dt'$. When $f$ and $g$ are monotonic and $h[f(\infty)] > \mu$, model (3) has a single steady state ($g_\star$, $p_\star$, $m_\star$) satisfying the fixed point equations

$$g_\star = \frac{1}{1 + c(p_\star)}, \quad m_\star = f(p_\star), \quad g_\star = \frac{h(m_\star) - \mu}{\lambda}. \quad (4)$$

Note that the steady state depends only on parameters $\lambda$ and $\mu$ as well as on functions $f$, $g$ and $h$, whereas parameters $\theta$, $\alpha$, $\delta$ control time scales. The behavior of the degradation and cooperativity functions in the neighborhood of the steady state is described by the slopes

$$s = \frac{df(p)}{dp} \bigg|_{p=p_\star}, \quad u = \frac{dh(m)}{dm} \bigg|_{m=m_\star}, \quad v = \frac{dc(p)}{dp} \bigg|_{p=p_\star}. \quad (5)$$

In the case of linear degradation [$f(p) = p, h(m) = m$], we have $u = s = 1$. Small or even negative values of the slopes $s$ and $u$ generally denote strongly nonlinear degradation mechanisms [2,23], including saturation.

To assess whether Eqs. (3) can display oscillations, we have searched for parameter values where the fixed point specified by (4) loses stability to a periodic solution via a Hopf bifurcation (i.e., a pair of conjugate eigenvalues of the linearized problem cross the imaginary axis). For simplicity, we assume perfect repression ($\mu = 0$) and a large threshold $P_0$ ($\alpha \approx 0$). Under this approximation, the Routh-Hürwitz stability criterion [25] indicates that a Hopf bifurcation occurs when the quantity

$$H = \sigma + (-\delta \lambda g \sigma^2 + \sigma^2) \tau + \gamma \sigma \tau^2 \quad (5)$$

crosses zero to become negative, where $\tau = g_\star/\theta$ is the gene response time, and the sum $\sigma = \delta s + u$ and product $\gamma = \delta \mu \tau^2$ are symmetric functions of degradation rates $\delta s$ and $u$. At bifurcation, the oscillation period is $\tau_{osc} = \frac{2\pi \sqrt{\tau(\sigma + \gamma \tau)}}{\sigma}$ where $\sigma$ and $\gamma$ satisfy $H = 0$. Cooperativity essentially changes the feedback strength from $\delta \lambda$ to $\delta \lambda \nu$; thus, we assume for simplicity single-protein regulation [$c(p) = p, \nu = 1$] thereafter.

Equation (5) shows that a strong feedback destabilizes the system while high degradation rates (large $\sigma$ and $\gamma$) tend to stabilize it. In the single-protein case, $H > 0$ when both protein and RNA are linearly degraded and no oscillations occur. Conversely, when protein and RNA degradations are completely saturated ($s = u = \sigma = 0$), $H = -\delta \lambda g^2 \tau < 0$, indicating that oscillations then appear systematically. The behavior in intermediate cases depends on the value of the response time $\tau$.

In the classical case $\tau = 0$, $H = \sigma$ and oscillations appear only for $\sigma < 0$. It is indeed known that negative effective degradation rates can lead to oscillations [2,23]. We thus restrict ourselves to showing that at finite $\tau$, oscillations can occur for $u, s > 0$. More precisely, we want to understand how oscillations arise away from the saturated cases $u = 0$ or $s = 0$. To this end, we use the geometric slope average $\nu = \sqrt{us} = \sqrt{\gamma/\delta}$ as an index ($\nu = 1$ in the linear case), seeking to determine the maximum value of $\nu$ at which oscillations can be observed, and for which values of $\tau$ this extremum is achieved.

The quantities $\sigma$ and $\gamma$ play complementary roles. The total degradation rate $\sigma$ controls instability onset for small to moderate $\tau$. Moreover, Eq. (5) indicates that when $\sigma, \gamma > 0$, a necessary condition for oscillations is
where \( t_{sw} \) is the time during which a fully active gene synthesizes the amount of protein corresponding to half-repression threshold. The degradation rate product \( \gamma \) is relevant only for large \( \tau \), blocking oscillations if it is too large. In particular, \( \gamma = 0 \) guarantees the onset of oscillations for sufficiently large \( \tau \) whenever (6) holds. For \( \nu, s \geq 0 \) and a given value of \( \sigma \), \( \gamma \) can take any value between \( \sigma^2/4 \) and 0 depending on whether the two degradation rates are equal or completely unbalanced, one being equal to zero and the other to \( \sigma \). We use below \( \epsilon = 2\sqrt{\gamma}/\sigma \in [0,1] \) as a balance indicator.

Remarkably, we note that under the rescaling

\[
\sigma = \sigma_c \Sigma, \quad \gamma = \sigma_c^2 \left( \frac{\Sigma}{2} \right)^2, \quad \tau = \frac{T}{\sigma_c},
\]

the oscillation condition can be rewritten without explicit parameter dependence

\[
\mathcal{H}_\epsilon(\Sigma, T) = \mathcal{H} \times \left[ \frac{\epsilon^2 \Sigma^2}{4} \tau^2 + \left( \frac{\Sigma}{2} \right)^2 \right] < 0
\]

and defines a series of curves \( \Sigma_{\epsilon}(T) \) such that given a balance index \( \epsilon \) and a response time \( T \), oscillations are found for \( \Sigma \leq \Sigma_{\epsilon}(T) \). Figure 2 shows the limit curves \( \Sigma_1(T) \) and \( \Sigma_0(T) \) which are important to understand the bifurcation diagram: regardless of the value of \( \epsilon \), the circuit always (never) oscillates when \( \Sigma < \Sigma_1(T) \) \( \Sigma > \Sigma_0(T) \).

To support our analysis, we have searched the parameter space of Eqs. (3) for oscillatory behavior for \( \alpha, \mu \neq 0 \), assuming for definiteness allosteric protein degradation and Michaelis-Menten RNA degradation

\[
f(p) = \frac{p \times (a + p/\kappa)}{a + 2a(p/\kappa) + (p/\kappa)^2}, \quad h(m) = \frac{\chi m}{\chi + m}.
\]

Points in the \( (\Sigma, T) \) plane associated with oscillating parameter sets are shown as black dots in Fig. 2. Agreement is excellent: all dots are below the \( \Sigma_0(T) \) curve and the few significantly above \( \Sigma_1(T) \) have one small degradation rate. We are thus confident that our analysis allows us to understand the behavior of Eqs. (3).

Two regions can be distinguished in Fig. 2. For \( T < 1 \), the instability threshold \( \Sigma_0(T) \) is practically independent of \( \epsilon \) and increases rapidly with \( T \). For small \( T \), \( \Sigma_1(T) - \Sigma_0(T) \) (thus, the oscillation criterion is \( \sigma < \sigma_c^2 \)). In the \( T > 1 \) region, \( \Sigma_0(T) \) reaches its maximum value \( \Sigma_m(\epsilon) = 1/\sqrt{\epsilon} + 1 \) at \( T = T_m(\epsilon) = 2\sqrt{\epsilon} \) + 1/\( \epsilon \), and then decreases as \( T^{-1} \) for \( T \to \infty \), except for \( \epsilon = 0 \) where it monotonically increases towards \( \Sigma = 1 \). At fixed \( \Sigma_0 \), oscillations are thus found in a finite range of \( T \), which widens gradually, and is eventually infinite, as \( \epsilon \to 0 \).

In the oscillation region, the index \( \nu \sim \epsilon \Sigma \), measuring distance from saturated degradation reaches its maximal value \( \nu_{\text{opt}} = g_s \sqrt{\delta \lambda}/8 \) for \( T = T_{\text{opt}} = 2\sqrt{2} \) and \( \epsilon = 1 \), at the maximum of the \( \Sigma_1(T) \) curve. Our analysis thus unveils a resonance phenomenon in the dynamics of a self-regulated gene with dynamical transcription rate: this circuit bifurcates most easily to periodic behavior, or more generally is least stable, at a finite value of the gene relaxation time given by \( \tau_{\text{opt}} = 2\sqrt{2} \tau_c \), where

\[
\tau_c = \frac{1}{g_s \sqrt{\delta \lambda}} = \frac{1}{\sigma_c g_s \sqrt{2}} = \frac{t_{sw}}{g_s \sqrt{2}} = \frac{\delta_M}{g_s^2} \times \frac{1}{g_s \sqrt{2}} \frac{P_0}{\lambda_0 \beta_0}.
\]

The quantity \( \tau_c \) gives the time scale at which dynamical behavior departs from the fast regulation case. Because \( g_s \) is determined by (4), computing precise lower bounds on \( \tau_c \) with (10) requires specifying the degradation mechanisms. Fixing \( \lambda_0 = \beta_0 = 10 \text{ mm}^{-1}, P_0 = 100, \) and \( g_s = 0.5 \), provides an estimate \( t_c = \tau_c / \delta_M = 2 \text{ mm} \) which is not unrealistically larger than typical gene induction times. At resonance, the oscillation period is \( \tau_{\text{osc}} = 4\pi \sqrt{2}/3 \tau_c \) (corresponding to about 20 mm in the example above).

Since a common interpretation of the diagram of Fig. 1 is that there are only two gene states (bound or unbound) [26], one may wonder whether our deterministic analysis is relevant. If \( \gamma \) is viewed as a temporal average of gene activity, our results are valid when the response time \( \tau \) is small compared to the oscillation period so that there are many binding or unbinding events by cycle [27]. Moreover, transcription is a complex process involving a number of distinct steps [4], and Eq. (1a) is the simplest way to model memory effects arising from cooperativity in the transcription machinery [6].

Anyway, we now show that even when \( G \) is a stochastic variable jumping between 0 and 1, our main result still
holds: there is a time scale near $\tau_{\text{opt}}$ at which oscillations are enhanced. To this end we have carried out stochastic simulations of the reaction network of Fig. 1 using the Gillespie algorithm [28], varying the response time $\tau$ at fixed $P_0$. Instead of regular oscillations, a sequence of irregularly spaced peaks in protein concentration is observed. A natural question is then whether protein peaks occur more regularly at parameter values where the deterministic model oscillates, in particular, when $\tau = \tau_{\text{opt}}$.

We define interpeak times as the time intervals $\Delta t$ between two crossings of $P = 1.2 P_{\text{avg}}$, separated by at least one crossing of $P = 0.8 P_{\text{avg}}$, with $P_{\text{avg}}$ the mean protein level (thus imposing a minimum amplitude of 40%). Their distribution is characterized by the coefficient of variation $\eta = \frac{\tau_{\text{opt}}}{\Delta t}$. A typical variation of $\eta$ with $\tau$ in our system is shown in Fig. 3. It definitely suggests that the deterministic analysis remains relevant in the stochastic regime, since there is clearly a time scale near $\tau_{\text{opt}}$ where interpeak time fluctuations are minimal.

In conclusion, we have shown that a nontrivial transcriptional dynamics can destabilize a self-regulated gene. Although it is known that strongly nonlinear degradation mechanisms can induce oscillations in this system, we observe a resonancelike effect such that a much weaker nonlinearity is required when the gene response time matches a characteristic time. Its expression can be computed analytically, which allows us to identify the parameter regions where this effect cannot be neglected. Stochastic simulations confirm the relevance of this time scale in the dynamics of the self-regulated gene. This shows that transcriptional dynamics is a possible source of oscillatory behavior besides other deterministic [1–3, 13, 14, 18–20, 23] and stochastic [29, 30] effects.

A natural question is whether our conclusions remain valid when more detailed transcriptional mechanisms or multiple sources of delay are taken into account. It can be shown that adding an explicit delay to Eqs. (3) only further destabilizes the circuit and thus does not essentially interfere with the effect of a gene response delay. Future studies should thus focus on cases where the transcriptional dynamics is more complex and features more than one limiting step.
